

Diabetic Readmission Analysis

Objective:

Analyze factors associated with hospital readmissions among diabetic patients, focusing on age, length of stay, and prior inpatient visits.

Key Findings:

- Readmission rates increase with age but stabilize across adult groups
- Longer hospital stays are associated with slightly higher readmission rates
- Prior inpatient visits show the strongest relationship with readmission risk

Conclusion:

Prior healthcare utilization appears to be the most significant predictor of readmission risk among diabetic patients. Patients with frequent prior inpatient visits consistently show higher readmission rates, suggesting that hospitals should prioritize early intervention strategies for these high-risk individuals. Potential approaches include enhanced discharge planning, closer outpatient follow-up, and care coordination programs targeting patients with a history of repeated hospitalizations.
